Testing Multivariate Economic Restrictions Using Quantiles: The Example of Slutsky Negative Semidefiniteness

September 27, 2013

Abstract

This paper is concerned with testing rationality restrictions using quantile regression methods. Specifically, we consider negative semidefiniteness of the Slutsky matrix, arguably the core restriction implied by utility maximization. We consider a heterogeneous population characterized by a system of nonseparable structural equations with infinite dimensional unobservable. To analyze this economic restriction, we employ quantile regression methods because they allow us to utilize the entire distribution of the data. Difficulties arise because the restriction involves several equations, while the quantile is a univariate concept. We establish that we may test the economic restriction by considering quantiles of linear combinations of the dependent variable. For this hypothesis we develop a new empirical process based test that applies kernel quantile estimators, and derive its large sample behavior. We investigate the performance of the test in a simulation study. Finally, we apply all concepts to Canadian microdata, and show that rationality is not rejected.

Keywords: Nonparametric Testing, Heterogeneity, Integrability, Nonseparable Models, Consumer Demand, Quantile Regression.

1 Introduction

Economic theory yields strong implications for the actual behavior of individuals. In the standard utility maximization model for instance, economic theory places strong restrictions on individual responses to changes in prices and wealth, the so-called integrability constraints. These restrictions are inherently restrictions on individual level: They have to hold for every preference ordering and every single individual, at any price wealth combination. Other than obeying these restrictions, the individuals' idiosyncratic preference orderings may exhibit a lot of differences. Indeed, standard parametric cross section mean regression methods applied to consumer demand data often exhibit $R^2$ between 0.1 and 0.2. Today, the consensus is that the majority of the unexplained variation is precisely due to unobserved preference heterogeneity. For this reason, the literature has become increasingly interested in exploiting all the information about unobserved heterogeneity contained in the data, in particular using the quantiles of the dependent variable.

To lay out our model, let $y$ denote the $L - 1$ vector of quantities demanded. At this stage, we have already imposed the adding up constraint (i.e., out of $L$ goods we have deleted the last). Let $p$ denote the $L$ vector of prices, and $x$ denote income (total expenditure)$^1$. For every individual, define the cost function $C(p, u)$ to give the minimum cost to attain utility level $u$ facing the $L$-vector of prices $p$, and given income (more precisely, total outlay) $x$. The Slutsky negative semidefiniteness restriction arises from the fact that the cost function is concave, and hence the matrix of second derivatives is negative semidefinite (nsd, henceforth). For brevity, we will sometimes equate negative semidefiniteness with "rationality", even though it is only one facet of rationality in this setup with linear budget constraint$^2$.

Obviously, this hypothesis has to hold for any preference ordering $u$. However we do not observe the individual's preference ordering $u$, and only observe a $K$ dimensional vector of household covariates (denoted $q$). Specifically, we assume to have $n$ iid observations on individuals from an underlying heterogeneous population characterized by random variables $U, Y, X, P, Q$ which have a nondegenerate joint distribution $F_{U, Y, X, P, Q}$.

The question of interest is now as follows: What can we learn from the observable part of this distribution, i.e. $F_{Y, X, P, Q}$, about whether the Slutsky matrix is negative semidefinite across a heterogeneous population, for all values of $(p, x, u)$? In Hoderlein (2011), we consider testing

---

$^1$This is the income concept commonly used in consumer demand. It is motivated by the assumption of separability of preferences over time and from other decisions (e.g., the labor supply decision). We use the phrases "total expenditure", "income" and "wealth" interchangeably throughout this paper.

$^2$Since negative semidefiniteness is arguably the core rationality restriction, we feel that this shortcut is justified, but we would like to alert the reader to this.
negative semidefiniteness in such a setting with mean and second moment regressions only. However, these lower order moment regressions have the disadvantage that they use only one feature of \( F_{Y,X,P,Q} \), and not the entire distribution. Therefore, in this paper we propose to exploit the distributional information by using all the \( \alpha \)-quantiles of the conditional distribution of observables, which (with varying \( \alpha \)) employ all the information that may be obtained from the data about the economic hypothesis of interest.

There are two immediate difficulties now, and solving them is the major innovation this paper introduces. The first is how to relate a specific economic property in the (unobservable) world of nonseparable functions to observable regression quantiles. The second one is how to use quantiles in systems of equations. The solution for the second difficulty is to consider linear combinations of the dependent variable, i.e. \( Y(b) = b'Y \) for all vectors \( b \) of unit length and consider the respective conditional \( \alpha \)-quantiles of this quantity. This can be thought of as an analogue to the Cramer-Wold device, and is a strategy that is feasible more generally, e.g., when testing omission of variables. As \( b \) and \( \alpha \) vary, we exploit the entire distribution of observables. The solution to the first of these two difficulties involves obviously identifying assumptions. To this end, since we are dealing with nonseparable models we require full conditional independence, i.e., we require that \( U \perp (P,X)|Q \), or versions of this assumption that control for endogeneity. These assumptions are versions of the “selection on observables” assumptions in the treatment effect literature. Essentially they require that, in every subpopulation defined by \( Q = q \), preferences as well as prices and income be independently distributed. Although endogeneity is not relevant for our application, our treatment covers the control function approach to handle endogeneity in nonseparable models discussed in Altonji and Matzkin (2005), Imbens and Newey (2009) or Hoderlein (2011), by simply adding endogeneity controls \( V \) to the set of household control variables \( Q \). From now on, we denote by \( W \) the set of all observable right hand side variables, i.e., \( (P',X,Q') \), and potentially in addition \( V \), if we are controlling for endogeneity\(^3\).

Under this assumption and some regularity conditions, our first main contribution is as follows: We establish that the untestable rationality hypothesis in the underlying population has a testable implication on the distribution of the data, specifically, on the conditional quantiles of linear combinations of the dependent variables. Consequently, we can test a null hypothesis in the underlying (unobservable) heterogeneous population model in the sense that a rejection of the testable implication leads also to a rejection of the original null hypothesis. While this procedure controls size, though likely conservative, it may suffer from low power: If we do not

\(^3\)In classical consumer demand, it is typically income that is considered endogenous, see the discussion in section 2.
reject the implication, we cannot conclude that the data could not have been generated by some other, nonrational mechanism. This is the price we pay for being completely general, as the only material assumption that we require to relate the observable object and the underlying heterogeneous population is the conditional independence assumption $U \perp (P, X) \mid Q$, and no other material assumption on the functional form of demand or their distribution enters the model. In particular, we have not assumed any monotonicity or triangularity assumption; there can be infinitely many unobservables, and they can enter in arbitrarily complicated form; in a sense, every individual can have its own nonparametric utility function, and hence this framework is closer to a random functions setup.

Our second main contribution is proposing a quantile regression based nonparametric test statistic. Specifically, we apply the sample counterparts principle to obtain a nonparametric test statistic of the testable implication, and derive its' large sample properties. We show weak convergence of a corresponding standardized stochastic process to a Gaussian process and obtain an asymptotically valid hypothesis test. Moreover, we propose a bootstrap version of our test statistic which is based on a centered version of the stochastic process to avoid the generation of bootstrap observations under the null. We adapt the well known idea of residual bootstrap for our specific model and provide arguments for the validity of the bootstrap. Nonparametric tests involving quantiles are surprisingly scant, and we list the closest references in the following paragraph. Specifically, in a system of equations setup we are the first to propose a quantile based test of an economic hypothesis, and to implement such a test using real world data.

Our test is a pointwise test, meaning that it holds locally for $W = W_0$. The main reason for this is that we aim at a more detailed picture of possible rejections, providing a better description of the rationality of the population (e.g., one outcome is that negative semidefiniteness is rejected for 20% of the population (= representative positions at which the test is evaluated)). An alternative is a test that integrates over a certain range of $W$, a strategy which increases power at the expense of a less detailed picture of the population. We feel that both strategies are justified, and leave the latter for future work.

**Literature** Testing the key integrability constraints that arise out of utility maximization dates back at least to the early work of Stone (1954), and has spurned the extensive research on (parametric) flexible functional form demand systems (e.g., the Translog, cf. Jorgenson, Lau and Stoker (1982), and the Almost Ideal, cf. Deaton and Muellbauer (1980)). Nonparametric

---

4 At an intermediate stage, we could consider the behavior of the test at a fixed grid of values $w_1, \ldots, w_B$. Since the pointwise estimators at the different grid points are asymptotically independent, the present theory extends straightforwardly, and merely results in a more cumbersome notation. This is why we desist from this here.
analysis of some derivative constraints was performed by Stoker (1989) and Härdle, Hildenbrand and Jerison (1991), but none of these has its focus on modeling unobserved heterogeneity. More closely related to our approach is Lewbel (2001) who analyzes integrability constraints in a purely exogenous setting, but does not use distributional information nor suggests or implements an actual test. An alternative method for checking some integrability constraints is revealed preference analysis, see Blundell, Browning and Crawford (2003), and references therein. An approach that combines revealed preference arguments with a demand function structure is Blundell, Kristensen and Matzkin (2011). As a side result, this paper develops a test of the weak axiom of revealed preferences, but in contrast to our paper, this paper assumes a scalar unobservable that enters monotonically in a single equation setup.

While our approach extends earlier work on demand systems, it is very much a blueprint for testing all kinds of economic hypothesis in systems of equations. Due to the nonseparable framework we employ, our approach extends the recent work on nonseparable models - in particular Hoderlein (2011), Hoderlein and Mammen (2007), Imbens and Newey (2009), Matzkin (2003). When it comes to dealing with unobserved heterogeneity, there are two strands in this literature: The first assumes triangularity and monotonicity in the unobservables (Chesher (2003), Matzkin (2003)). The triangularity and monotonicity assumptions are, however, rather implausible for consumer demand, because in general the multivariate demand function is a nonmonotonic function of an infinite dimensional unobservable - the individuals’ preference ordering - and all equations depend on this object.

Hence we follow the second route. Extending earlier work in Hoderlein (2011), Hoderlein and Mammen (2007) establish interpretation of the derivative of the conditional quantile (a scalar valued function!) if there is more than one unobservable. The upshot of this work is that in a world with many different sources of unobserved heterogeneity, at best conditional average effects are identified, see also Altonji and Matzkin (2005) and Imbens and Newey (2009).

In the statistics literature, the closest work we are aware of includes the testing procedures proposed by Zheng (1998), Sun (2006), Escanciano and Velasco (2010), and Dette, Wagener and Volgushev (2011), which all consider some versions of tests on regression quantiles, but there is no clear direct relationship. Finally, Wolak (1991) considers testing of inequality constraints in nonlinear parametric models. These tests are very different from ours due to the general difference between testing in parametric and nonparametric environments.

In this paper we work with quantiles of univariate linear combinations of the multivariate observations. In the literature several different approaches to define quantiles of multivariate random variables have been suggested, see Barnett (1976), Serfling (2002) and Koenker (2005) for overviews, and Hallin, Paindaveine and Siman (2010) and Belloni and Winkler (2011) for
more recent approaches.

Structure of the Paper: The exposition of this paper is as follows. In the next section, we introduce our model formally, state some assumptions, and derive and discuss the main identification result. In the third section, we propose a nonparametric test for the economic hypothesis of Slutsky nsd based on the principle of sample counterparts, analyze its large sample behavior and propose a bootstrap procedure to derive the critical values. We investigate the performance of the bootstrap procedure for moderate sample sizes in a simulation study in section 4. In the fifth section, we apply these concepts to Canadian expenditure data. The results are affirmative as far as the validity of the integrability conditions are concerned and demonstrate the advantages of our framework. A summary and an outlook conclude this paper, while the appendix contains regularity assumptions, proofs, graphs and summary statistics.

2 Deriving Quantile Restrictions of Economic Behavior in a Heterogeneous Population

2.1 Building Blocks of the Model and Assumptions

Our model of consumer demand in a heterogeneous population consists of several building blocks. As is common in consumer demand, we assume that - for a fixed preference ordering - there is a causal relationship between physical quantities, a real valued random $L$-vector denoted by $Y$, and regressors of economic importance, namely prices $P$ and total expenditure $X$, real valued random vectors of length $L$ and 1, respectively, stemming from utility maximization subject to a linear budget constraint. More specifically, in slight abuse of notation, we define the Marshallian demand function for an individual with preferences $u \in U$, where $U$ is a preference space, e.g., the space of $r$ times continuously differentiable utility functions, to be $y = \psi(p, x; u)$. We consider Slutsky nsd for a $(L - 1) \times (L - 1)$ submatrix of the Hessian of the cost function, denoted $D_{p-L} \psi(p, x; u) + \nabla_x \psi(p, x; u) \psi(p, x; u)' = \mathcal{S}(p, x, u) = (s^{jk}(p, x, u))_{1 \leq j \leq L-1, 1 \leq k \leq L-1}$, where $p_{-L}$ denotes the price vector without the $L$-th price. If this submatrix of second derivatives is not nsd, the complete matrix involving all $L$ equations cannot be nsd either. The null hypothesis in the underlying unobservable heterogeneous populations is hence that $b'\mathcal{S}(p, x, u)b \leq 0$, for all $b \in S_{L-1}$ (where here and throughout $S_d$ denotes the $d$-dimensional unit sphere) and any $(u, p, x) \in U \times \mathbb{R}^{L+1}$. The hypothesis of Slutsky nsd translates therefore to an inequality restriction on an $L - 1$ dimensional system of equations, where each equation is characterized by a nonseparable model. As already mentioned, we assume a linear budget constraint as well
as nonsatiation of preferences, which implies the adding up constraint. To avoid the singularity associated with this constraint, we impose it from the outset, so that we obtain an $L - 1$ vector of dependent variables. We also assume homogeneity of degree zero, so that we can omit the $L$-th price (that of the residual category, prices have from now on dimension $L - 1$), all prices are relative to the residual price, and total expenditure is normalized to be real total expenditure.

To capture the notion that preferences vary across the population, we assume that there is a random variable $U \in \mathcal{U}$, where $\mathcal{U}$ is a Borel space\footnote{Technically: $\mathcal{U}$ is a set that is homeomorphic to the Borel subset of the unit interval endowed with the Borel $\sigma$-algebra. This includes the case when $U$ is an element of a polish space, e.g., the space of random piecewise continuous utility functions.}, which denotes preferences (or more generally, decision rules). In this setup, all individuals could be of the same type, e.g., Cobb Douglas, with varying parameters, but they could also have their own type each, which is the notion that we think is most realistic. We assume that heterogeneity in preferences is partially explained by observable differences in individuals’ attributes (e.g., age), which we denote by the real valued random $K$-vector $Q$. Hence, we let $U = \vartheta(Q, A)$, where $\vartheta$ is a fixed $\mathcal{U}$-valued map defined on the sets $Q \times A$ of possible values of $(Q, A)$, and where the random variable $A$ (taking again values in a Borel space $A$) covers residual unobserved heterogeneity in a general fashion. To fix ideas, think of $A$ as the genom of an individual.

As already mentioned, we want to allow for infinitely many individual preference orderings each of which may be characterized by finite or infinite dimensional parameter. Therefore we formalize the heterogeneous population as $Y = \psi(P, X, U) = \phi(P, X, Q, A)$, for a general map $\phi$ and an infinite dimensional vector $A$. Obviously, neither $\phi$ nor the distribution of $A$ are nonparametrically identified. Still, for any fixed value of $A$, say $a_0$, we obtain a demand function having standard properties. Moreover, to show that our approach can handle endogeneity which arises because economic decisions are related, we treat the more general case and introduce additional instruments, denoted $S$. The prototypical example for endogeneity in a consumer demand setting is total expenditure $X$ (“income”), in parts because individual expenditures are often large categories that are mismeasured, and hence the aggregate expenditure measure is mismeasured, too. The typical instrument $S$ is the wage rate, because it impacts total expenditure in any given period via a life cycle planning argument, but is determined on the market largely outside the individual’s influence. As the main breadwinner’s labor supply is often assumed to be inelastic, the argument extends to labor income which is often used alternatively, see Lewbel (1999). However, the argument could also be extended to some other source of endogeneity, say, in the own price. To keep the exposition simple, we focus on the scalar endogenous variable case, i.e. we assume that it is only $X$ that is endogenous, and that
there is exactly one additional instrument $S$. Note, however, that in our application endogeneity does not play a major role, and this is done solely for expositional purposes.

The first assumption collects all definitions and specifies the DGP formally:

**Assumption 1.** Let $(\Omega, \mathcal{F}, P)$ be a complete probability space on which are defined the random vectors $A : \Omega \to \mathcal{A}, \mathcal{A} \subseteq \mathbb{R}^\infty$, and $(Y, P, X, Q, S, V) : \Omega \to \mathcal{Y} \times \mathcal{P} \times \mathcal{X} \times Q \times \mathcal{S} \times \mathcal{V}, \mathcal{Y} \subseteq \mathbb{R}^{L-1}, \mathcal{P} \subseteq \mathbb{R}^{L-1}, \mathcal{X} \subseteq \mathbb{R}, Q \subseteq \mathbb{R}^K, S \subseteq \mathbb{R}, V \subseteq \mathbb{R}$, with $L$ and $K$ finite integers, such that

\[
Y = \phi(P, X, Q, A),
\]

\[
X = \mu(P, Q, S, V)
\]

where $\phi : \mathcal{P} \times \mathcal{X} \times Q \times A \to \mathcal{Y}$ and $\mu : \mathcal{P} \times Q \times S \times V \to \mathcal{X}$ are Borel functions, and realizations of $(Y, P, X, Q, S)$ are observable, whereas those of $(A, V)$ are not. Moreover, $\mu$ is invertible in its last argument, for every $(p, q, s)$.

Assumption A1 defines the nonparametric demand system with (potentially) endogenous regressors as a system of nonseparable equations. These models are called nonseparable, because they do not impose an additive specification for the unobservable random terms (in our case $A$). They have been subject of much interest in the recent econometrics literature (Chesher (2003), Matzkin (2003), Altonji and Matzkin (2005), Imbens and Newey (2009), Hoderlein (2011), Hoderlein and Mammen (2007), to mention just a few). Since we do not assume monotonicity in unobservables and allow the error to be infinite dimensional, our approach is more closely related to the latter four approaches. As is demonstrated there, in the absence of strict monotonicity of $\phi$ in $A$, the function $\phi$ is not identified, however, local average structural derivatives are. Although it will be demonstrated that identification may proceed on this level of abstraction, in the case of endogeneity of $X$ this requires, however, that $V$ be solved for because these residuals have to be employed in a control function fashion. In the application, we specify $\mu$ to be the conditional mean function, and consequently $V$ to be the additive mean regression residuals, but this is only one out of several possibilities. We conjecture that alternative approaches are possible where one restricts the dimension of the error in the outcome equation at the expense of an unrestricted IV equation. Since in our application endogeneity turns out not to be an issue, we do not want to extend the discussion unnecessary.

Given that we have all major elements of our model defined and in place, we specify the independence conditions required for identification. We introduce the notation $Z = (Q', V')$, and $\mathcal{Z} = \mathcal{Q} \times \mathcal{V}$.

**Assumption 2.** The random vectors $A$ and $(P, X)$ are independent conditional on $Z$. 

Assumption \textbf{A2} is the only material assumption that we require in order to identify the marginal effect of interest, and thus being able to analyze the economic restriction of interest, in our case Slutsky negative semidefiniteness. Therefore it merits a thorough discussion: Assume for a moment all regressors were exogenous, i.e. \( S \equiv X, Z \equiv Q \) and \( V \equiv 0 \). Then this assumption states that wealth and prices be independently distributed of unobserved heterogeneity \( A \), conditional on individual attributes.

To give an example: Suppose that in order to determine the effect of wealth on consumption, we are given data on the demand of individuals, their wealth and the following attributes: “education in years” and “gender”. Take now a typical subgroup of the population, e.g., females having received 12 years of education. Assume that there be two wealth classes for this subgroup, rich and poor, and two types of preferences, type 1 and 2. Then, for both rich and poor women in this subgroup, the proportion of type 1 and 2 preferences has to be identical for all levels of wealth. This assumption is of course restrictive. Note, however, that preferences and economically interesting regressors may still be correlated across the population. Moreover, any of the \( Z \) may be correlated with preferences, in particular \( Q \), i.e., household characteristics.

Finally, if it is suspected that regressors and unobservables are not independent, we may still introduce instruments in a control function fashion.

In the following, to make the exposition less dense we make use of the notation \( W = (P', X, Q', V')' \). Moreover, for a given vector \( b \) we introduce the conditional quantile \( k(\alpha, b|w) \) of the distribution of \( Y(b) = b'Y \), given \( W = w \), i.e. for \( 0 < \alpha < 1 \) the quantity \( k(\alpha, b|w) \) is defined by \( \mathbb{P}(Y(b) \leq k(\alpha, b|w) \mid W = w) = \alpha \), or, upon substitution,

\[
\mathbb{P}(b'\phi(p, x, q, A) \leq k(\alpha, b|w) \mid W = w) = \alpha,
\]

where \( w = (p', x, q', v') \). We will also require a set of regularity assumptions, largely differentiability and boundedness conditions, which can be found in the appendix (see assumption \textbf{A3}). Given these assumptions and notations, we concentrate first on the relation of theoretical quantities and identified (and hence estimable) objects. Specifically, we are concerned with the question of how quantiles allow inference on key elements of economic theory. In particular, we want to learn about negative semidefiniteness of the Slutsky matrix. In the standard consumer demand setup we consider, the Slutsky matrix in the underlying heterogeneous population (defined by \( \phi, x \) and \( v \)), takes the form

\[
\mathcal{S}(p, x, u) = D_p\psi(p, x, u) + \partial_x\psi(p, x, u)\psi(p, x, u)'
\]

for all \((p, x, u) \in \mathcal{P} \times \mathcal{X} \times \mathcal{U}\),

where \( D \) denotes the matrix of second derivatives with respect to price, and \( \partial \) denotes the vector of partial derivatives with respect to income. Slutsky negative semidefiniteness is an implication
of the weak axiom of revealed preferences, and given smooth and differentiable demands, it is “almost” equivalent in the sense that the usual weak axiom is equivalent to Slutsky negative definiteness (i.e., $\mathbb{S} < 0$), and Slutsky negative semidefiniteness is equivalent to a weak version of the weak axiom that allows for weak inequalities in both defining equations, see Kihlstrom, Mas Colell and Sonnenschein (1976). Since we think of our framework as one with continuously distributed demands and utility functions, the difference is likely a set of measure zero in any such application. Hence we will loosely refer to both concepts as equivalent, even though theoretically they are not.

The following theorem provides an answer about what we can learn from regression quantiles.

**Theorem 1.** Let assumptions $A1$–$A3$ hold. Then

$$\mathbb{S}(p, x, u) \nsd \Rightarrow \nabla_p k(\alpha, b|w)'b + \partial_x k(\alpha, b|w)k(\alpha, b|w) \leq 0$$

for all $(\alpha, b) \in (0, 1) \times S_{L-1}$, and all $(p, x, u, z) \in \mathcal{P} \times \mathcal{X} \times \mathcal{U} \times \mathcal{Z}$. Moreover,

$$\nabla_p k(\alpha, b|w)'b + \partial_x k(\alpha, b|w)k(\alpha, b|w) = \mathbb{E}[b'\mathbb{S}b \mid W = w, Y(b) = k(\alpha, b|w)].$$

**Discussion of Theorem 1:** This result establishes the link between negative semidefiniteness in a heterogeneous population characterized by complicated and nonmonotonic heterogeneity, and the joint distribution of the data as characterized by the various regression quantiles of $Y(b)$ for all $b \in S_{L-1}$. As already discussed above, it characterizes all we can learn from data about the economic hypothesis of interest, and also characterizes the object by which we do, i.e., $\mathcal{F}(\alpha; p, x, z) = \nabla_p k(\alpha, b|p, x, z)'b + \partial_x k(\alpha, b|p, x, z)k(\alpha, b|p, x, z)$. To see the economic content of $\mathcal{F}(\alpha; p, x, z)$, note that the second part of the theorem establishes that this quantity is related to the LASD of Hoderlein (2011), and Hoderlein and Mammen (2007). To continue with our economic example, suppose again we were given data on consumption, wealth, “education in years” and “gender” as above. Then by considering $\mathcal{F}(\alpha; b, p, x, z)$, we may identify, for fixed $b$, the average over the Slutsky matrix of a subpopulation characterized by a certain level of prices, wealth and covariates, e.g., all female high school graduates earning 50K, whose value of a weighted average of their demands has a certain value. However, due to the pervasive and complex unobserved heterogeneity, we are not able to identify the Slutsky matrix of every single individual. Thus, since we consider $b'Y$, our averages use more information than simply the one embedded in the regressors; by variation of $b$ we consider these averages across the entire distribution of the data and hence use all information available.

There are limitations to this approach that employs minimal assumptions and these limitations suggest interesting directions for future research. One particular issue is the following: The
equality in theorem 1 provides testable implications for each fixed value \((p, x, z)\), and all quantiles. In this setup, even the entire information contained in the joint distribution of observables does not suffice to trace out the distribution of unobservables - there is “excess” heterogeneity, i.e., we cannot invert the distribution of observables for the distribution of unobservables as is for instance the case in triangular models and linear random coefficient models. Put reversely, the joint distribution of \((W, Y(b))\) is still an integral over the underlying complex structural relationship, where integration is with respect to “many” unobservables that are generally correlated with \(Q\) and \(Y(b)\). Hence, the integral operation, in fact a conditional averaging operation, is not invertible. Absent additional functional form or homogeneity assumptions, this average is the most we can learn from the data, we cannot learn about the individuals’ behavior.

One important implication is loss of power. To see this, assume \(\mathcal{G}(P; X; U)\) is a.s.-symmetric to avoid imaginary Eigenvalues. Then, since \(\mathcal{F}(\alpha, b|w) = E[b\mathcal{G}(p; x; U)b|W = w]\), for all \(b \in S_{L-1}\), it is impossible for \(\mathcal{F}(\alpha, b|w)\) to be non-positive for all \(b \in S_{L-1}\), even if \(\mathcal{G}(P; X; U)\) is positive definite \(U|W = w\)-a.s., i.e., the conditional average cannot be non-positive, if not at least a small set of positive measure \(\mathcal{G}\) is negative semidefinite. If \(\mathcal{F}(\alpha, b|w)\) is non-positive for all \(b \in S_{L-1}\), the subpopulation with \(W = w\) may either be entirely rational (i.e., \(H'_0: \mathcal{G}(P; X; U)\) is negative semidefinite \(U\)-a.s. holds), or it may be comprised of two subpopulations, the just mentioned rational population, and another one that defies rationality. Whether or not this second population exists cannot be determined from looking at the aggregate statistic \(\mathcal{F}(\alpha, b|w)\) alone. Formally, we have, for all \(b \in S_{L-1}\):

\[
E[b\mathcal{G}(p; x; U)b|W = w] = E[b\mathcal{G}(p; x; U)b|W = w, \mathcal{G} \text{ not nsd}] \mathbb{P}[\mathcal{G} \text{ not nsd}|W = w] \\
+ E[b\mathcal{G}(p; x; U)b|W = w, \mathcal{G} \text{ nsd}] \mathbb{P}[\mathcal{G} \text{ nsd}|W = w],
\]

and if the left hand side is non-positive, it could arise from \(\mathbb{P}[\mathcal{G} \text{ not nsd}|W = w]\) or from the fact that the positive first average of the nonrational population is, in our language “overcompensated” by the negative average of the rational part of the subpopulation, weighted with their respective probabilities. Alternatives that are indistinguishable from \(H'_0\) are therefore all necessarily of the type where the second term dominates the first, and \(\mathbb{P}[\mathcal{G} \text{ not nsd}|W = w] > 0\).

3 From Hypothesis to Test Statistic

In this section we assume we have observed independent data \((Y_i, P_i, X_i), i = 1, \ldots, n\), with the same distribution as \((Y, P, X) \in \mathbb{R}^{L-1} \times \mathbb{R}^{L-1} \times \mathbb{R}\). We do not treat the additional conditioning on \(Z_i\) as standard nonparametric results extend straightforwardly to this setup by simply adapting the rates appropriately and - in the case of \(V\) - having generated regressors, whose estimation
does not affect first order asymptotics if we are willing to assume enough smoothness in the
regression of endogenous regressors on instruments, see Sperlich (2009). Since including $Z$ only
makes the notation more cumbersome, all results extend in a straightforward fashion, and we
consider a homogeneous subpopulation in our application, we omit it from now on.

For each fixed $w = (p, x) \in \mathbb{R}^{L-1} \times \mathbb{R}$ we want to test negative semi-definiteness of the Slutsky
matrix. To this end we use the notations

$$k_{p_\ell}(\alpha, b \mid w) = \partial_{p_\ell}k(\alpha, b \mid w)$$
$$k_x(\alpha, b \mid w) = \partial_xk(\alpha, b \mid w),$$

where $k(\alpha, b \mid w)$ denotes again the $\alpha$-quantile of the conditional distribution of $Y(b) = b'Y$, given $W = (P, X) = w$. As we have seen from the previous subsection, the null hypothesis of
rationality transforms to

$$H_0 : \sum_{\ell=1}^{L-1} b_\ell k_{p_\ell}(\alpha, b \mid w) + k_x(\alpha, b \mid w)k(\alpha, b \mid w) \leq 0 \quad (3.1)$$
$$\forall \alpha \in (0, 1), b = (b_1, \ldots, b_{L-1})' \in \mathcal{S}_{L-1}.$$

Now let $\mathcal{A}$ be any closed subset of $(0, 1)$. We define the test statistic by

$$T_n = \sqrt{nh^{L+2}} \sup_{(\alpha, b) \in \mathcal{A} \times \mathcal{S}_{L-1}} R_n(\alpha, b \mid w), \quad (3.2)$$

where

$$R_n(\alpha, b \mid w) = \sum_{\ell=1}^{L-1} b_\ell \hat{k}_{p_\ell}(\alpha, b \mid w) + \hat{k}_x(\alpha, b \mid w)\hat{k}(\alpha, b \mid w). \quad (3.3)$$

Here, with notations $W_i = (P'_i, X'_i)$ and $\tau_\alpha(u) = u(\alpha - I\{u < 0\})$, the estimators are obtained
from the kernel quantile estimation approach

$$ (\hat{\mu}_0, \hat{\mu}_1, \hat{\mu}_2)$$

$$= \arg \min_{(\mu_0, \mu_1, \mu_2) \in \mathbb{R} \times \mathbb{R}^{L-1} \times \mathbb{R}^{L-1}} \sum_{i=1}^n \tau_\alpha \left( Y'_i b - \mu_0 - \mu'_1(W_i - w) - (W_i - w)'\mu_2(W_i - w) \right) K \left( \frac{W_i - w}{h} \right)$$

as $\hat{k}(\alpha, b \mid w) = \hat{\mu}_0$, $\hat{k}_{p_\ell}(\alpha, b \mid w) = \hat{\mu}_{1,\ell}$, $\ell = 1, \ldots, L-1$, and $\hat{k}_x(\alpha, b \mid w) = \hat{\mu}_{1,L}$, see Yu and

Under the conditions stated in assumption $\textbf{A4}$ in the appendix, $R_n(\alpha, b \mid w)$ consistently estimates

$$R(\alpha, b \mid w) = \sum_{\ell=1}^{L-1} b_\ell k_{p_\ell}(\alpha, b \mid w) + k_x(\alpha, b \mid w)k(\alpha, b \mid w)$$

and we have the following weak convergence result.
Theorem 2. The process
\[ \sqrt{nh^{L+2}} \left( R_n(\alpha, b \mid w) - R(\alpha, b \mid w) \right)_{\alpha \in \mathbb{A}, b \in S_{L-1}} \]
converges (for \( w \) fixed) weakly in \( L^\infty(\mathbb{A} \times S_{L-1}) \) to a Gaussian process \( G(\alpha, b \mid w)_{\alpha \in \mathbb{A}, b \in S_{L-1}} \) with covariance
\[
\text{Cov} \left( G(\alpha, b \mid w), G(\tilde{\alpha}, \tilde{b} \mid w) \right) = \left[ \mathbb{P} \left( Y(b) \leq k(\alpha, b \mid w), Y(\tilde{b}) \leq k(\tilde{\alpha}, \tilde{b} \mid w) \mid (P, X) = w \right) - F_{Y(b)\mid P,X} \left( k(\alpha, b \mid w) \mid w \right) F_{Y(\tilde{b})\mid P,X} \left( k(\tilde{\alpha}, \tilde{b} \mid w) \mid w \right) \right] \\
\times \frac{\int K^2(\bar{p}, \bar{x})(\bar{b}^T \bar{p} + k(\alpha, b \mid w)\bar{x})(\bar{b}^T \bar{p} + k(\tilde{\alpha}, \tilde{b} \mid w)\bar{x}) d(\bar{p}, \bar{x})}{f_{Y(b)\mid P,X}(k(\alpha, b \mid w) \mid w) f_{Y(\tilde{b})\mid P,X}(k(\tilde{\alpha}, \tilde{b} \mid w) \mid w) f_{P,X}(w)(\int u^2 k(u) du)^2},
\]
where \( f_{P,X} \) denotes the density of \((P, X)\) and \( f_{Y(b)\mid P,X}(\cdot \mid w), F_{Y(b)\mid P,X}(\cdot \mid w) \) denote the conditional density and distribution function of \( Y(b) \), given \((P, X) = w\), respectively.

From the theorem we cannot obtain the asymptotic distribution of the test statistic \( T_n \) under \( H_0 \) to approximate critical values for the test, but we obtain the asymptotic distribution of a “centered” version, i.e.
\[ \tilde{T}_n = \sqrt{nh^{L+2}} \sup_{\alpha \in \mathbb{A}, b \in S_{L-1}} \left( R_n(\alpha, b \mid w) - R(\alpha, b \mid w) \right) \quad (3.4) \]
both under the null hypothesis and under fixed alternatives. As corollary from Theorem 2 it follows that, for each \( c \in \mathbb{R} \),
\[ \mathbb{P}(\tilde{T}_n > c) \xrightarrow{n \to \infty} \mathbb{P} \left( \sup_{\alpha \in \mathbb{A}, b \in S_{L-1}} G(\alpha, b) > c \right). \quad (3.5) \]
Because of the specific structure of the null hypothesis, \( H_0 : R(\cdot, \cdot \mid w) \leq 0 \), it follows that \( \mathbb{P}(T_n > c) \leq \mathbb{P}(\tilde{T}_n > c) \) under \( H_0 \) and, hence, we obtain an asymptotically level \( \gamma \) test by rejecting \( H_0 \) whenever \( T_n > c_\gamma \), where \( \mathbb{P}(\sup_{\alpha,b} G(\alpha, b) > c_\gamma) = \gamma \). Note that this construction may lead to conservative testing procedures. Furthermore, for the techniques used in the proof of theorem 2 we need \( \alpha \) to be bounded away from the boundaries of \((0, 1)\) (see, e.g., assumption 4 (iv) and (v) and note that \( k(0, b \mid w) = -\infty, k(1, b \mid w) = \infty \) for distributions with positive density on \( \mathbb{R} \)). This means that alternatives where the inequality in (3.1) is violated for some \( \alpha \in (0, 1) \setminus \mathbb{A} \) cannot be detected. However, this is less of a concern, since in practise it makes sense to bound \( \alpha \) away from zero and one, because very small and very large quantiles cannot be estimated accurately. In the simulations and data example we used \( \mathbb{A} = (0.05, 0.95) \).
Because of the complicated covariance structure in Theorem 2, in applications we suggest to approximate the asymptotic quantile \( c_\gamma \) by the following bootstrap procedure. The idea of any bootstrap procedure for testing hypotheses for independent samples is to generate new data \((Y^*_k, P^*_k, X^*_k), k = 1, \ldots, n\) (independent, given the original sample \((Y_i, P_i, X_i), i = 1, \ldots, n\)) which follow a model as similar as possible to the original data model under the null hypothesis. However, given the specific structure of the null hypothesis it is not clear how to generate data that fulfill \( H_0 \). Instead we use bootstrap versions of the “centered” test statistic \( \hat{T}_n \) as follows. As is common in regression models, to generate new data we keep the covariates and define \((P^*_k, X^*_k) = (P_k, X_k)\). For each fixed covariate \((P_k, X_k)\) we then generate \( Y^*_k \) from a distribution which approximates the conditional distribution of \( Y \), given \((P, X) = (P_k, X_k)\), i.e. \( F_{Y|P,X}(\cdot \mid P_k, X_k) \). Note that for one-dimensional observations \( Y \) this method coincides with the bootstrap procedure suggested in Hoderlein and Mammen (2009), and consistency may be established along similar lines. To estimate the conditional distribution \( F_{Y|P,X}(\cdot \mid P_k, X_k) \) we apply the usual kernel approach and define

\[
\hat{F}_{Y|P,X}(y \mid P_k, X_k) = \sum_{i=1}^{n} I\{Y_{i,1} \leq y_1, \ldots, Y_{i,L-1} \leq y_{L-1}\} \frac{k(\frac{W_i-W_k}{g})}{\sum_{j=1}^{n} k(\frac{W_j-W_k}{g})}
\]

for \( y = (y_1, \ldots, y_{L-1}), Y_i = (Y_{i,1}, \ldots, Y_{i,L-1}), i = 1, \ldots, n \), with kernel function \( k \) and bandwidth \( g \). The bootstrap version of the test statistic \( T_n \) defined in (3.2) is

\[
T^*_n = \sqrt{n h^{L+2}} \sup_{\alpha \in \mathbb{A}, b \in S_{L-1}} \left( R^*_n(\alpha, b \mid w) - R_n(\alpha, b \mid w) \right), \tag{3.6}
\]

where \( R_n \) is defined in (3.3) and \( R^*_n \) is defined analogously, but based on the bootstrap sample \((Y^*_k, P^*_k, X^*_k), k = 1, \ldots, n\). Both under the null hypothesis and under alternatives, the conditional distribution of \( T^*_n \), given the original sample, approximates the distribution of \( \hat{T}_n \) defined in (3.4) and (3.5). We approximate the asymptotic quantile \( c_\gamma \) by \( c^*_n,\gamma \), where

\[
\mathbb{P}\left(T^*_n > c^*_n,\gamma \mid (Y_i, P_i, X_i), i = 1, \ldots, n\right) = \gamma.
\]

With the same argument as before (under regularity conditions given in appendix II in A4 and some assumptions on the kernel \( k \) and bandwidth \( g \)) we obtain an asymptotically level \( \gamma \) test by rejecting \( H_0 \) whenever \( T_n > c^*_n,\gamma \). Moreover, the test is consistent (against alternatives where the inequality (3.1) is violated for some \( \alpha \in \mathbb{A}, b \in S_{L-1} \)), because under a fixed alternative \( \sup_{b,\alpha} R_n(b, \alpha \mid w) \) converges to \( \sup_{b,\alpha} R(b, \alpha \mid w) > 0 \) in probability, such that \( T_n \) converges to infinity. On the other hand, \( c^*_n,\gamma \) approximates the \((1 - \gamma)\)-quantile of \( \hat{T}_n \) which converges to \( c_\gamma \in \mathbb{R} \) by (3.5). Hence, the probability of rejection converges to one.
4 Monte Carlo Experiments

To analyze the finite sample performance of our test statistic and to get a feeling for the behavior of the test in our application, we simulate data from a joint distribution that has similar features at least in terms of observables. We specify the DGP to be a linear random coefficients specification, which is arguably the most straightforward model of a heterogeneous population, and choose the distributions of coefficients such that under the null the entire population is rational, while under the alternative there is a fraction that does not have a negative semidefinite Slutsky matrix. We apply the test developed above to answer the question whether there is a significant fraction that does not behave rationally.

More specifically, to test whether $H_0$ in (3.1) is valid, we first estimate $T_n$ as described in equation (3.2) and the following passage. In particular, in (3.3) we use a local quadratic estimator with a product kernel where the individual kernels are standard univariate Epanechnikov kernels. The bandwidth is selected by using a slightly larger bandwidth than the bandwidth that is selected by cross validation of the corresponding nonparametric median regression, to account for the fact that we largely use derivatives. Since our simulation setup is calibrated to the application, we use somewhat differing variances for the respective regressors, see below. To account for this when choosing the bandwidth, we scale the individual bandwidths for every dimension by multiplying with the standard deviation $\sigma_{W_j}$ of the respective regressor $W_j$, i.e., the bandwidth for dimension $j$ is of the form $h_j = h \sigma_{W_j}$, and $h$ is selected by cross validation to be approximately 0.25.

To obtain the distribution of $T_n^\ast$ from (3.6) we apply the same estimators, but now use 100 bootstrap samples generated as described in section 3. The bandwidth we use is slightly smaller than the one used in estimation (by a factor of 0.8)$^6$. Since $b$ is supposed to have unit length, the grid of $b$s is chosen such that $b_1^2 + b_2^2 + b_3^2 = 1$, and $b_j^2 \in \{0, 0.1, ..., 0.9, 1\}$, for all $j$. We have evaluated all quantile regressions at a set of 15 equally spaced positions, i.e., $A = \{0.05, ..., 0.95\}$ of $\alpha$-quantiles of $Y(b)$, for every $b$. We design the test to have nominal level of 0.05, as mentioned above we will have a slight size distortion by construction. This completes the description of the econometric tools we apply, and we now turn to the details of the data generating process:

To keep the results simple and transparent, we assume that the data generating process contains no income effect, and only prices $P = (P_1, P_2, P_3, P_4)'$, $P \sim \mathcal{N}(\mu_P, \Sigma_P)$, where $\mu_P = (1, 1, 1, 1)'$ and $\Sigma_P = diag(1.6, 1.1, 1.1, 1.6)$. This is justified as the income effects turn out to be rather minor in our application, because the individual categories account for moderate sections of

$^6$We have performed some robustness checks by varying the bandwidth, and the results were insensitive to moderate changes.
total expenditures only, and the income elasticities are not very large, see the next section.
In addition to the stochastic regressors, the DGP contains random heterogeneity parameters
\( A = (A_0, A_1, A_2, A_3, A_4)' \), independent of \( P \), for which we specify that \( A \sim N(\mu_A, \Sigma_A) \). We choose \( \mu_A = (20, 20, 20, 30, 10)' \); the second to fourth reproduce the average absolute values
of the own price effects of prices 1-3 in our application, and \( \Sigma_A = \text{diag}(5, 5, 5, 5, 2) \) in the low variance setup, and \( \Sigma_A = \text{diag}(5, 10, 5, 5, 2) \). Those values are chosen, together with the random
coefficients \( A_0 \) and \( A_4 \), to roughly reproduce the \( R^2 \) in the respective regressions. Moreover, we
assume that there is a fixed parameter \( \lambda \in \mathbb{R}^+ \) which we introduce to model deviations from
the null of rationality (negative semidefinite).

The quantities \( Y = (Y_1, Y_2, Y_3)' \) are then generated as

\[
\begin{bmatrix}
Y_1 \\
Y_2 \\
Y_3
\end{bmatrix} =
\begin{bmatrix}
1.5(A_0 - 20) + 20 \\
A_0 \\
0.8A_0
\end{bmatrix} +
\begin{bmatrix}
-A_1 + \lambda & 0.4A_2 & 0 \\
0.2A_1 & -A_2 & 0 \\
0 & 0 & -A_3
\end{bmatrix}
\begin{bmatrix}
P_1 \\
P_2 \\
P_3
\end{bmatrix} +
\begin{bmatrix}
A_4
\end{bmatrix}
P_4,
\]

Observe that in this model the Slutsky matrix is given by:

\[
\Sigma(A) =
\begin{bmatrix}
-A_1 + \lambda & 0.4A_2 & 0 \\
0.2A_1 & -A_2 & 0 \\
0 & 0 & -A_3
\end{bmatrix}.
\]

For \( \lambda = 0 \), the entire population is rational, i.e., its Slutsky matrix is negative semidefinite.
However, as \( \lambda \) increases, parts of the population become indefinite, which in the language of this
paper means that they cease to be rational. The following table illustrates how the proportion
of the population which is not rational increases, as illustrated by the largest (nonnegative)
eigenvalue of the symmetrized version of the Slutsky matrix:

<table>
<thead>
<tr>
<th>% Population not Rational</th>
<th>0</th>
<th>10</th>
<th>15</th>
<th>17.5</th>
<th>20</th>
<th>22.5</th>
<th>25</th>
<th>30</th>
</tr>
</thead>
<tbody>
<tr>
<td>( \lambda = 0 )</td>
<td>0.0001</td>
<td>0.041</td>
<td>0.250</td>
<td>0.443</td>
<td>0.647</td>
<td>0.822</td>
<td>0.928</td>
<td>0.996</td>
</tr>
</tbody>
</table>

This exercise corresponds to a mean shift in the distribution of the first random coefficient. Al-
ternatively, more nonrational types may also be generated by increasing the variance, however,
for the above reason (proximity to our application), we focus on this specification. From this
model, we draw an iid sample of \( n = 3000 \) observations.

The following table shows the result of our procedure as described in the previous paragraphs,
with \( n = 3000 \) observations, a bandwidth of 0.25, and at mean values of the regressors, \( \mu = \)
(1, 1, 1, 1). The size of the test is 0.03, and the power is displayed at the following alternatives:

<table>
<thead>
<tr>
<th>λ =</th>
<th>10</th>
<th>15</th>
<th>17.5</th>
<th>20</th>
<th>22.5</th>
<th>25</th>
<th>30</th>
</tr>
</thead>
<tbody>
<tr>
<td>% Population not Rational</td>
<td>0.041</td>
<td>0.250</td>
<td>0.443</td>
<td>0.647</td>
<td>0.822</td>
<td>0.928</td>
<td>0.996</td>
</tr>
<tr>
<td>Power</td>
<td>0.170</td>
<td>0.310</td>
<td>0.420</td>
<td>0.590</td>
<td>0.770</td>
<td>0.900</td>
<td>0.970</td>
</tr>
</tbody>
</table>

Figure 1 in the appendix gives a graphical representation of these results, as function of λ, while fig. 2 displays the power as a function of the proportion of the population that violates rationality. If we increase the bandwidth somewhat, the results do not change significantly, however, eventually the power decreases. In contrast, the results are sensitive to the choice of bandwidth in the sense that we get size distortions if we choose too small a bandwidth, more precisely, the size becomes 0.110. The following table shows the result of decreasing \( h \) from 0.25 to 0.2.

<table>
<thead>
<tr>
<th>λ =</th>
<th>10</th>
<th>15</th>
<th>17.5</th>
<th>20</th>
<th>22.5</th>
<th>25</th>
<th>30</th>
</tr>
</thead>
<tbody>
<tr>
<td>% Population not Rational</td>
<td>0.041</td>
<td>0.250</td>
<td>0.443</td>
<td>0.647</td>
<td>0.822</td>
<td>0.928</td>
<td>0.996</td>
</tr>
<tr>
<td>Power</td>
<td>0.190</td>
<td>0.310</td>
<td>0.390</td>
<td>0.580</td>
<td>0.770</td>
<td>0.880</td>
<td>0.940</td>
</tr>
</tbody>
</table>

The results are graphically compared in fig. 3 in the appendix. Finally, to show the consistency of the test, we display the result with \( n = 6000 \). At the now somewhat smaller bandwidth of \( h = 0.2 \), we obtain a size of 0.04 and the following results on power:

<table>
<thead>
<tr>
<th>λ =</th>
<th>10</th>
<th>15</th>
<th>17.5</th>
<th>20</th>
<th>22.5</th>
<th>25</th>
<th>30</th>
</tr>
</thead>
<tbody>
<tr>
<td>% Population not Rational</td>
<td>0.041</td>
<td>0.250</td>
<td>0.443</td>
<td>0.647</td>
<td>0.822</td>
<td>0.928</td>
<td>0.996</td>
</tr>
<tr>
<td>Power</td>
<td>0.240</td>
<td>0.380</td>
<td>0.530</td>
<td>0.640</td>
<td>0.800</td>
<td>0.910</td>
<td>0.980</td>
</tr>
</tbody>
</table>

We also perform the result for \( n = 1500 \), and they show a comparable decrease in power. A graph summarizing power as a function of \( n \) is displayed in fig. 4 in the appendix. Obviously the test exhibits power and is consistent for \( \alpha \) bounded away from zero and one\(^7\). Moreover, the power should also be seen in the context that the true model is a linear random coefficient model. It is well known from the nonseparable models literature that there is a tight connection between quantiles and nonlinear models with one monotonic heterogeneity factor, a class of models that is very different from our DGP. Finally, note that these deviations from rationality are rather mild; even amongst the non rational people most of the individuals exhibit small

\(^7\)As already mentioned, this means that the test is not consistent against alternatives where the inequality in (3.1) is violated for some \( \alpha \in (0,1) \setminus A \). However, this is less of a concern, since in our application it makes sense to bound \( \alpha \) away from zero and one, because very small and very large quantiles cannot be estimated accurately.
positive values of the Slutsky matrix. It is easy to design Monte Carlo experiments in which a larger positive eigenvalue of a small fraction of the population would generate even more power for our test, however, we do not believe that this represents a feature of our application, and hence desist from doing so here. In summary, we would also not expect that our test exhibits too much power against this specification, and the results appear reasonable.

However, this specification of the DGP allows easier comparison with standard practise, without which our results are hard to interpret. Since, to the best of our knowledge, there is no work which even mildly resembles what we propose, we compare our approach with a stylized version of standard parametric methods in this setup. Specifically, we run a parametric regression using a FGLS approach. Given our setup, the FGLS estimator incorporates the entire information about the model, as it is the ML estimator\(^8\). We then compute the largest eigenvalue of the Slutsky matrix, say, \(\hat{\lambda}\). Finally, we implement a bootstrap procedure to obtain standard errors, which is appropriate if there is no multiplicity of eigenvalues. The point estimate of the largest eigenvalue for \(\lambda = 17.5\) is \(-0.871\), with 95% confidence interval \([-1.189; -0.549]\). For \(\lambda = 22.5\), the point estimate is 3.809, with 95% confidence interval \([3.480; 4.129]\).

To perform a one-sided test, we moreover construct critical values \(CV = 2\hat{\lambda} - Q(.95, F_{\hat{\lambda}^2 - \hat{\chi}^2})\), where \(Q(.95, F_{\hat{\lambda}^2 - \hat{\chi}^2})\) denotes the 95% quantile of \(F_{\hat{\lambda}^2 - \hat{\chi}^2}\). For \(\lambda = 17.5\), we obtain an average \(CV = -1.193\), and zero rejections, whereas for \(\lambda = 22.5\), we obtain an average \(CV = 3.488\) with universal rejections. Standard practise would hence not reject, if 45% of the population is not rational and always reject with 80% nonrational individuals. The reason for this difference is that the parametric approach implicitly aggregates, and rejects only if the aggregate is sufficiently non rational after which it always rejects due to its small standard errors. This is different from our approach, which at least conditions on all observable information, and hence provides a smoother function in the fraction of nonrational people.

An interesting conclusion out of this comparison is that standard practise in parametric models picks up deviations from rationality only if it has finally an impact on the mean. In contrast, our test exhibits power already if the fraction of the population being not rational is rather small (e.g., with 4% non rational individuals and \(n = 6000\), a typical size in a cross section application, we reject one quarter of times). Rather than significant parts of the population being wildly non rational, we believe that at best parts of the population deviate from rationality in a rather mild fashion, and given the simulation results we feel comfortable that our test will be able to detect these deviations in an application, at least if we perform it at a large set of independent positions. Let us therefore now turn to such an application.

\(^8\)We are indebted to Dennis Kristensen for this suggestion
Finally, to bridge the gap to the empirical application, we modify the effective sample size in the 3 price dimensions to be \( n = 100 \), while we retain \( n = 3000 \) observations in total (each price gets merely repeated 30 times). This is common in many applications which feature prices or other aggregate variables as regressors. Unsurprisingly given the small effective sample, the size and power diminishes considerable, however, somewhat surprisingly at very low percentages of non rational population more than at high percentages. The size reduces to 0.02, while the power is displayed in the following table:

<table>
<thead>
<tr>
<th>( \lambda )</th>
<th>10</th>
<th>15</th>
<th>17.5</th>
<th>20</th>
<th>22.5</th>
<th>25</th>
<th>30</th>
</tr>
</thead>
<tbody>
<tr>
<td>% Population not Rational</td>
<td>0.041</td>
<td>0.250</td>
<td>0.443</td>
<td>0.647</td>
<td>0.822</td>
<td>0.928</td>
<td>0.996</td>
</tr>
<tr>
<td>Power</td>
<td>0.070</td>
<td>0.140</td>
<td>0.310</td>
<td>0.450</td>
<td>0.730</td>
<td>0.860</td>
<td>0.970</td>
</tr>
</tbody>
</table>

In the last graph (Fig.5) we compare this exercise with the behavior for \( n = 3000 \) independent observations, which nicely illustrate the pronounced differences in decay.

5 Empirical Implementation

In this section we discuss all matters pertaining to the empirical implementation: We give a brief sketch of the econometrics methods, an overview of the data, mention some issues regarding the econometric methods, and present the results.

5.1 Econometric Specifications and Methods

5.2 Data

The data used in this paper come from the following public use sources: (1) the Canadian Family Expenditure Surveys 1969, 1974, 1978, 1982, 1984, 1986, 1990, 1992 and 1996; and (2) the Surveys of Household Spending 1997, 1998 and 1999. These data contain annual expenditures in approximately 100 categories for 5 000 to 15 000 households per year. We use only households in cities with 30 000 or more residents (to match commodity price data and to minimize the effects of home production); Moreover, we also focus on households with rental tenure, to avoid rent imputation. Finally, we focus on households whose members are all full-year members under the age of 65, whose heads are aged 25 to 64. Price data, which is not present in the primary data sets for all these commodity groups (except rent) are available from Browning and Thomas (1999) for the 1969 to 1996 period and in Pendakur (2002) for the period from 1997 to 1999. Price and expenditure data are hence available for 12 years in 5 regions (Atlantic, Quebec, Ontario, Prairies and British Columbia), yielding 60 distinct price
vectors. Rent prices for the corresponding periods are from CANSIM (see Pendakur (2002) for details). Prices are normalized so that the price vector facing residents of Ontario in 1986 is \((1, \ldots, 1)\). The data is hence a repeated cross section; every individual is only sampled once. Table 1 gives (unweighted) summary statistics for 6952 observations of rental-tenure unattached individuals aged 25-64 with no dependents. Estimated nonparametric densities (not reported, but available from the authors) for log-prices and log-expenditures are approximately normal, as is typically found in the demand literature. Analysis is restricted to these households to minimize demographic variation in preferences. Demographic variation could be added to the model by conditioning all levels, log-price derivatives and log-expenditure derivatives on demographic covariates. Rather than pursue this strategy, we use a sample with very limited demographic variation.

The empirical analysis uses annual expenditure in four expenditure categories: Food at home, Food Out, Rent and Clothing. This yields three independent expenditure share equations which depend on 4 prices and expenditure. These four expenditure categories account for about half the current consumption of the households in the sample in total, and are henceforth called “Total Expenditure”. Estimation of this sub-demand system is only valid under the assumption of weak separability of the included four goods from all the excluded goods. As is common in the estimation of consumer demand, we invoke weak separability for the estimation that follows, but do not test it.

As another descriptive means to characterize the data, we report the results of three log-log mean regressions. In our framework, the coefficients do at best reflect some averages of effects
(in the case of endogeneity, not even this is warranted), and are only meant to be informative, as well as provide consistency checks for the data.

Table A.1 reports the result of the regression of log food in on the four log prices and log total expenditure. The own price elasticity is around -1, which is in line with reported results for other good (e.g., gasoline, see Hausman and Newey (1995)). Food in and food out are strong gross substitutes, as is to be expected, while the substitution patterns with the other goods are much less pronounced. In fact, if anything, rent and food in seem to be complements; a fact that may be related to a common lifestyle. Finally, the rather low total expenditure elasticity is also well documented in other studies, see Lewbel (1999) for an overview. It is shared by other necessities, e.g., gasoline (Hausman and Newey (1995)). Given the large number of observations, the estimates are fairly precise.

The other two regressions mirror these findings. Food out is less of a necessity than food in, consequently, its own price elasticity is larger in absolute values, see table A.2. Moreover, there is only a very weak relationship between food out and rent, which is confirmed by both regressions in tables A.2 and A.3. In both instances, the total expenditure elasticities are larger in absolute value, which is not surprising given that satiation is less of an issue with food out and rent, which consequently have more of a luxury character. The own price elasticities are both solidly negative and dominate in absolute value.

Linear quantile regressions essentially reproduce these results. As an example, we have included the median regression of food out on the same variable in table A.4. Obviously, the results are very comparable. The variations across quantiles are also surprisingly low. In particular, the dominant negative diagonal in the Slutsky matrix is well preserved throughout the range of quantiles. Though our analysis is nonparametric, uses levels as opposed to logarithms, and considers the compensated as opposed to the uncompensated price effect matrix, the descriptive results foreshadow our main finding: the data are largely consistent with the Slutsky matrix being negative semidefinite across the population.

Finally, as regards endogeneity of total expenditure: Haag, Hoderlein and Pendakur (2009) do not find evidence of endogeneity of total expenditure, the relevant income definition in this setup (see Lewbel (1999)), in this data set. Specifically, Haag, Hoderlein and Pendakur (2009) estimate the residuals in the IV equation nonparametrically, and then use these residuals in a nonparametric regression of the various demands on total expenditure as additional regressors. Using a standard nonparametric omission of variables test, they do not find the residuals to be significant. We hence do not pursue any control function strategy in this paper (even though it would be straightforward given the theoretical results).
5.3 Methodology and Results

As discussed in previous sections, we consider the statistic $R_n$ defined in (3.3), where for the kernel quantile estimator we use a product of standard Epanechnikov kernels. The bandwidth is selected by using a slightly larger bandwidth than the bandwidth that was selected by cross validation of the corresponding nonparametric median regression, to account for the fact that we largely use derivatives. More specifically, we scaled the individual bandwidths for every dimension by multiplying by the empirical standard deviation of the respective regressor, i.e., the bandwidth for dimension $j$ is of the form $h_j = h\sigma_{W_j}$, and $h$ was selected by cross validation to be 0.85. Given that features of the simulation were chosen to coincide with the data, this suggests that the model deviates significantly from the random coefficient model with normally distributed coefficients; if we force the bandwidth to be closer to zero we obtain very unstable behavior.

Standard errors were obtained via the bootstrap, as described in section 3, the bandwidth we used was slightly smaller than the one used in estimation (by a factor of 0.8). We have used 100 bootstrap replications, the grid of $b$s was selected as in section 4, and we have evaluated all quantile regressions at the same equally spaced grid of 15 support points, i.e., the set $A = \{0.05, ..., 0.95\}$ of quantiles of $Y(b)$, for every $b$ satisfying the above normalization condition. Moreover, we impose homogeneity of degree zero, which means that we work with three relative prices (relative to clothing), and with normalized total expenditure.

When we apply this machinery to the data, we obtain the following results: On a grid of 64 values of $w$ whose outer limits contain roughly 95% of the population in terms of $W$, the point estimates for $T_n(\alpha, b \mid w)$ are largely negative, with only three insignificant exceptions. The point estimates range from $-5.166$ to $2.874$, with a mean of $-1.472$ and a median of $-1.638$. Most of the values are clustered around $-1.5$. Table 2 provides results at selected values of $W$. 

These affirmative results are then corroborated if we employ our formal analysis, as outlined and analyzed above and in the finite sample exercise. In particular, neither of the three positive values is significantly positive, the difference $T_n - c_\gamma$ is always below $-2.8$. Given the results we can of course not reject rationality at any of the subpopulations (i.e., values of independent variables) considered. Since we can think of these positions as being asymptotically independent, even with rather small fraction of the population we would expect occasional violations of rationality.

To check this analysis for robustness, we have performed various experiments: First, we have varied the size of the grid. However, a finer grid yields essentially the same results. Specifically, on a grid with 256 values, we find $T_n$ to be non-negative roughly 10% of the time, however, none of the values is larger than 2.95, and more importantly, $T_n - c_\gamma$ is always solidly negative. One interesting finding is that regions of non-negative $T_n$ are more clustered together than with a grid size of 64 points, implying that the asymptotic independence does not hold well in finite samples with a fine grid. We obtain similar findings in our second experiment, where instead of fixing $X$ at 1, roughly the center of the distribution, we also allow for smaller and larger values. Again, we find ca. 13% of the values to be non-negative, but never very large in value, and the $T_n - c_\gamma$ again to be solidly negative.

To account for the fact that we are testing many hypotheses at once, we could apply some form of generalized family wise error rate, see Romano, Shaik and Wolf (2010) for an overview. Since either of them would make us less likely to reject the null, yet we are already not rejecting the null, we do not perform such an exercise here. However, we do remark that in similar structured applications the multiple testing character might be worthwhile investigating.

</table>
Of course, our findings could merely be an issue of low power. In particular, some of the more positive values could be in fact significantly positive. However, as already discussed above, under the minimal assumptions this power issue is unavoidable. What could be done is to integrate/average over at least parts of the set of conditioning variables. Since the negative values vastly outweigh the positive, we would expect such an averaging would result in negative estimates, but we leave such an approach that would extend the work of Haag, Hoderlein and Pendakur (2009) to quantiles for future research.

6 Summary and Outlook

Rationality of economic agents is the central paradigm of economics. Yet, within this paradigm individuals can vary widely in their actual behavior; only the qualitative properties of individual behavior are constrained, but not the heterogeneity across individuals. Indeed, in many data sets there are large differences in observed consumer choices even for individuals which are equal in terms of their observed household covariates, like age, gender, educational background etc.

One of the core qualitative restrictions of Economics is the negative semidefiniteness of the Slutsky matrix. It is the core restriction arising out of (static) utility maximization subject to a linear budget constraint. This paper discusses how to test this property using the entire conditional distribution of the data when individuals are assumed to be rational, but otherwise are allowed to be completely different from each other. The key insight is that quantile regressions based on linear combinations of the original dependent variables may be used to test the property of interest. While some of the insights of this paper may be generalized to related questions like omission of variables in system of equations (e.g., supply and demand systems), our focus in this paper remains on negative semidefiniteness. We derive the large sample behavior of the specific test statistic we consider, and analyze its small sample behavior in a simulation study.

Our empirical findings emphasize the affirmative tendency in the studies of rationality in Blundell, Pashardes and Weber (1993), Hoderlein (2011), and Haag, Hoderlein and Pendakur (2009). Using Canadian data, we cannot reject negative semidefiniteness. As a caveat, we have seen from the simulation study that the test may not detect very small fractions of irrational individuals in the population. While this may be a minor issue given the large set of independent conditions we are considering, it should nevertheless be seen as encouragement to perform a similar analysis with other data sets. Also, it may be interesting to search for semiparametric structures, e.g., random coefficient models that allow to test negative semidefiniteness in
a heterogeneous population with tests of higher power. Similarly, the structure of panel data may be exploited with new models that are either more efficient due to a repeated observations structure, or less prone to model misspecification as they allow for correlated time invariant factors. We hope that this research will encourage future work in this direction.

**Acknowledgements** The authors have received helpful comments from the co-editor Han Hong, an anonymous associate editor and two anonymous referees, Andrew Chesher, Roger Koenker, Dennis Kristensen, Arthur Lewbel, Rosa Matzkin, Ulrich Mueller, Whitney Newey and Azeem Shaik, as well as seminar participants at Boston College, Princeton and the Conference on Nonparametrics and Shape Constraints at Northwestern University. We are particularly indebted to Krishna Pendakur to provide us with the data. We would also like to thank Martina Stein, who typed parts of this manuscript with considerable technical expertise. This work has been supported in part by the Collaborative Research Center “Statistical modeling of nonlinear dynamic processes” (SFB 823) of the German Research Foundation (DFG).

Appendix II - Assumptions

Regularity Conditions for Theorem 1

Assumption 3. For fixed values \((p^*, x^*, z^*) \in \mathcal{P} \times \mathcal{X} \times \mathcal{Z}\) and \(0 < \alpha < 1\) we will make use of the following assumptions:

(i) The conditional distribution of \(Y(b)\) given \((P, X, Z)\) is absolutely continuous w.r.t. the Lebesgue measure for \((p, x)\) in a neighborhood of \((p^*, x^*)\) and for \(z = z^*\).

(ii) The conditional density \(f_{Y(b)|P,X,Z}(y|p,x,z^*)\) of \(Y(b)\) given \((P,X,Z)\) is continuous in \((y,p,x)\) at the point \((k_\alpha(w^*;b),w^*)\).

(iii) The conditional density \(f_{Y(b)|P,X,Z}(y|w^*,z^*)\) of \(Y(b)\) given \(W = w^*\) is bounded in \(y \in \mathbb{R}\).

(iv) Let \(w_1 = (p',x')\). \(k_\alpha(w_1,z;b)\) is partially differentiable with respect to any component of \(w_1\) at \((w_1,z) = (w^*_1,z^*)\). Moreover, there exist measurable functions \(\Delta_k\), \(k = 1,\ldots,L\), satisfying

\[
P\left[|\phi(w^*_{1k} + \delta, w^*_{1k-1}, z^*, A) - \phi(w^*_1, z^*, A) - \delta \Delta_k(A)| \geq \varepsilon \delta_k \mid X = x^*\right] = o(\delta_k)
\]

for \(\delta_k \to 0\) and fixed \(\varepsilon > 0\). We write \(\partial_{w_{1k}} \phi(w^*_1, z^*, a)\) for \(\Delta_k(a)\) and \(\partial_{w_{1k}} \phi\) for \(\Delta_k(A)\), for all \(k = 1,\ldots,L\).

(v) The conditional distribution of \((Y(b), \partial_{w_{1k}} \phi)\), given \((P,X,Z)\), is absolutely continuous w.r.t. the Lebesgue measure for \((p,x,z) = (p^*,x^*,z^*)\) and all \((b,k)\). For the conditional density \(f_{Y(b),\partial_{w_{1k}} \phi|P,X,Z}(y,y'|p^*,x^*,z^*)\) given \((P,X,Z)\), we require that \(f_{Y(b),\partial_{w_{1k}} \phi|P,X,Z}(y,y'|p^*,x^*,z^*) \leq C g(y')\), where \(C\) is a constant and \(g\) a positive density on \(\mathbb{R}\) with finite mean (i.e. \(\int |y'| g(y') \, dy' < \infty\)).

Assumptions for Theorem 2

Assumption 4. In the following let \(\Lambda\) denote a closed subset of \((0,1)\) and \(\mathcal{S}_{L-1} = \{b \in \mathbb{R}^{L-1} \mid ||b|| = 1\}\). Let \(\mathcal{W} \subset \mathbb{R}^L\) denote the support of \(W = (P,X)\) and let \(w \in \mathcal{W}\) be fixed. Let \(F_{Y(b)|W}(\cdot \mid \hat{w})\) and \(f_{Y(b)|W}(\cdot \mid \hat{w})\) denote the conditional distribution and density functions of \(Y(b) = b'Y\), given \(W = \hat{w}\), respectively. For \(\delta > 0\), \(M > 0\), let \(C^\delta_M(\mathcal{W})\) denote the class of smooth functions with partial derivatives up to order \(\delta\) (the greatest integer smaller than \(\delta\)) uniformly bounded by \(M\), whose highest partial derivatives are Lipschitz continuous of order \(\delta - \delta\) [see van der Vaart and Wellner (1996), p. 154/155]. We will make use of the following assumptions:

(i) Let \(K\) be an \(L\)-variate product kernel of the univariate bounded symmetric density \(\kappa\) with bounded support such that \(\int_{\mathbb{R}} \kappa(u)u^2 \, du < \infty\).

(ii) Let \(h = h_n\) denote a sequence of positive bandwidths such that \(nh^{L(1+\frac{1}{n^2})} \rightarrow \infty\), \(nh^{L+0} \rightarrow 0\) for \(n \rightarrow \infty\).
(iii) Let \( W \) be compact and convex and let the density \( f_W \) of \( W \) be bounded away from zero in a neighborhood \( N \) of \( w \) and be bounded and continuous. Let the second moments of \( W \) exist.

(iv) Assume that the function \( A \times S_{L-1} \rightarrow \mathbb{R}, (\alpha, b) \mapsto F_Y(\alpha | b | w) \) is bounded by a constant \( C \) and uniformly continuous.

(v) For each fixed \( \tilde{w} \in W \) let the function \( A \times S_{L-1} \rightarrow \mathbb{R}, (\alpha, b) \mapsto F_Y(\tilde{w} | b | w) \) be continuous. Assume that there exist \( M > 0 \) and \( \delta > \frac{L}{2} \) such that for all \( c \in \mathbb{R}, |c| \leq C \) the function \( W \rightarrow \mathbb{R}, \tilde{w} \mapsto F_Y(\tilde{w} | b | w) \) belongs to \( C^M(W) \). Let the function \( (y, \tilde{w}) \mapsto f_Y(y | \tilde{w}) \) be uniformly continuous in \( y \) and \( \tilde{w} \) and be bounded and bounded away from zero. Further assume that \( \inf_{(\alpha, b, \tilde{w}) \in A \times S_{L-1} \times N} f_Y(\tilde{w} | b | w) > 0 \).

Appendix III - Proof of Theorem 1

Let \( A(\omega), \omega \in \Omega \), denote any random matrix. If \( b' A(\omega) b \leq 0 \) for all \( \omega \in \Omega \) and all \( b \in \mathbb{R}^L \), then, upon taking expectations w.r.t. an arbitrary probability measure \( F \), it follows that

\[
\int b' A(\omega) b F(d\omega) \leq 0 \iff \int A(\omega) F(d\omega) b \leq 0, \quad \text{for all } b \in S_{L-1}.
\]

From this, \( \mathcal{G}(p, x, u) \) nsd \( \Rightarrow \mathbb{E}[\mathcal{G}|P = p, X = x, Z = z, Y(b) = k(\alpha, b|w)] \) nsd for all \( (p, x; z) \in \mathcal{P} \times \mathcal{X} \times \mathcal{Z} \) is immediate. Let \( \mathbb{E}[\mathcal{G}|P, X, Z, Y(b)] = B \), and note that since the definition of negative semidefiniteness of a square matrix \( B \) of dimension \( L - 1 \) involves the quadratic form, \( b'Bb \leq 0 \). Next, observe that

\[
B = \mathbb{E}[\mathcal{G}|P = p, X = x, Z = z, Y(b) = k(\alpha, b|w)]
\]

\[
= \mathbb{E}[D_p \phi|P = p, X = x, Z = z, Y(b) = k(\alpha, b|w)]
\]

\[
+ \mathbb{E}[\partial_x \phi|P = p, X = x, Z = z, Y(b) = k(\alpha, b|w)]
\]

\[
= B_1 + B_2,
\]

as well as

\[
b'B_1 b = b' \mathbb{E}[D_p \phi|P = p, X = x, Z = z, Y(b) = k(\alpha, b|w)] b
\]

\[
= \mathbb{E}[\nabla_p \eta|P = p, X = x, Z = z, Y(b) = k(\alpha, b|w)] b
\]

\[
= \nabla_p k(\alpha, b|w)' b,
\]
where \( \eta = \phi' b \) and the last equality follows from the theorem in Hoderlein and Mammen (2007). Moreover, by arguments as above

\[
b' B_2 b = \mathbb{E} [b' \partial_x \phi' b | P = p, X = x, Z = z, Y(b) = k(\alpha, b|w)] \\
= \mathbb{E} [\partial_x \eta | P = p, X = x, Z = z, Y(b) = k(\alpha, b|w)] \\
= \mathbb{E} [\partial_x \eta | P = p, X = x, Z = z, Y(b) = k(\alpha, b|w)] k(\alpha, b|w) \\
= \partial_x k(\alpha, b|w) k(\alpha, b|w),
\]

where the second to last equality follows from \( Y(b) = \eta \) and the last equality again from Hoderlein and Mammen (2007). Using the definition of negative semidefiniteness,

\[
b' (B_1 + B_2) b \leq 0,
\]

we obtain,

\[
\nabla_p k(\alpha, b|w)' b + \partial_x k(\alpha, b|w) k(\alpha, b|w) \leq 0
\]

and the result follows. \( \square \)

### Appendix IV - Proof of Theorem 2

#### Auxiliary results

**Lemma 6.1.** Uniformly with respect to \( \alpha \in A, b \in S_{L-1} \) we have

\[
\sqrt{n} h^{L+2} \left( R_n(\cdot, \cdot | w) - R(\cdot, \cdot | w) \right) = \tilde{R}_n + o_p(1),
\]

where

\[
\tilde{R}_n(\alpha, b) = \sqrt{n} h^{L+2} \left( \sum_{\ell=1}^{L-1} b_\ell (\hat{k}_{p_\ell}(\alpha, b | w) - k_{p_\ell}(\alpha, b | w) + \hat{k}_x(\alpha, b | w) - k_x(\alpha, b | w)) k(\alpha, b | w) \right).
\]

**Proof of Lemma 6.1.** The assertion follows from uniform consistency of the estimator \( \hat{k}_x(\alpha, b | w) \) and

\[
\sup_{\alpha, b} |\hat{k}(\alpha, b | w) - k(\alpha, b | w)| = o_p(\frac{1}{\sqrt{n} h^{L+2}}).
\]

\( \square \)

**Lemma 6.2.** (Bahadur expansion) Uniformly with respect to \( \alpha \in A, b \in S_{L-1} \) we have

\[
\tilde{R}_n(\alpha, b) = -\frac{1}{\sqrt{n} h^{L+2}} \frac{1}{f_{Y(b)}|P,X}(k(\alpha, b | w) | w) f_W(w) \int u^2 k(u) du \sum_{i=1}^{n} K \left( \frac{W_i - w}{h} \right) \left( I \{ Y_i(b) \leq k(\alpha, b | w) \} - F_{Y(b)|W}(k(\alpha, b | w) | W_i) \right) \\
\times \left[ b'(P_i - p) + k(\alpha, b | w)(X_i - x) \right] + o_p(1).
\]
**Proof of Lemma 6.2.** Obviously it is sufficient to prove the representation for \( \hat{k}_{p_1}(\alpha, b \mid w) - k_{p_1}(\alpha, b \mid w) \), \( \ell = 1, \ldots, L - 1 \), and \( \hat{k}_x(\alpha, b \mid w) - k_x(\alpha, b \mid w) \) in the representation of \( \hat{R}_n(\alpha, b) \) in Lemma 6.1, and the assertion of the Lemma follows by building linear combinations. For the sake of brevity, we restrict ourselves to the first component of the vector \( P \); all other cases are treated in the same way.

Using similar arguments as in the proof of Theorem A.1 by Hoderlein and Mammen (2009) we obtain the expansion

\[
R_n^{(1)}(\alpha, b) = \sqrt{n h^{L+2}} (\hat{k}_{p_1}(\alpha, b \mid w) - k_{p_1}(\alpha, b \mid w))
\]

\[
= - \frac{1}{\sqrt{n h^{L+2}} f_{Y(b)|P,X}(k(\alpha, b|w)|w) f_W(w) \int u^2 \kappa(u) du}
\]

\[
\times \sum_{i=1}^{n} K\left(\frac{W_i - w}{n}\right) \left\{ I\{Y_i^*(b) < 0\} - \alpha \right\} (P_{1i} - p_1) + o_p(1)
\]

uniformly with respect to \( \alpha \in \mathbb{A}, b \in \mathcal{S}_{L-1} \), where \( P_{1i} \) denotes the first component of the vector \( P_i \) \( (i = 1, \ldots, n) \) and the random variables \( Y_i^*(b) \) are defined by \( Y_i^*(b) = Y_i(b) - \bar{K}_i(\alpha, b|w) \) with

\[
\bar{K}_i(\alpha, b, w) = k(\alpha, b|w) - \nabla_w k(\alpha, b|w)(W_i - w) - \frac{1}{2} (W_i - w)^T \nabla_{ww} k(\alpha, b|w)(W_i - w).
\]

This yields the decomposition

\[
R_n^{(1)}(\alpha, b) = - \frac{S_{1,n}(\alpha, b) + S_{2,n}(\alpha, b) + S_{3,n}(\alpha, b)}{f_{Y(b)|P,X}(k(\alpha, b|w)|w) f_W(w) \int u^2 \kappa(u) du},
\]

where

\[
S_{1,n}(\alpha, b) = \frac{1}{\sqrt{n h^{L+2}}} \sum_{i=1}^{n} K\left(\frac{W_i - w}{h}\right) (P_{1i} - p_1) \left\{ I\{Y_i(b) < k(\alpha, b|w)\} - \mathbb{P}(Y_i(b) < k(\alpha, b|w)|W_i) \right\}
\]

\[
S_{2,n}(\alpha, b) = \frac{1}{\sqrt{n h^{L+2}}} \sum_{i=1}^{n} K\left(\frac{W_i - w}{h}\right) (P_{1i} - p_1) \left\{ I\{Y_i^*(b) < 0\} - \mathbb{P}(Y_i(b) < k(\alpha, b|w)) - \mathbb{P}(Y_i^*(b) < 0|W_i) \right\}
\]

\[
S_{3,n}(\alpha, b) = \frac{1}{\sqrt{n h^{L+2}}} \sum_{i=1}^{n} K\left(\frac{W_i - w}{h}\right) (P_{1i} - p_1) \left\{ \mathbb{P}(Y_i^*(b) < 0|W_i) - \alpha \right\}.
\]

Obviously we have \( E[S_{2,n}(\alpha, b)] = 0 \) and for the variance of this random variable we obtain by a straightforward but tedious calculation

\[
\text{Var}(S_{2,n}(\alpha, b)) \leq \frac{1}{h^{L+2}} E \left[ K^2\left(\frac{W_i - w}{h}\right) (P_{1i} - p_1)^2 E[(I\{Y_i^*(b) < 0\} - I\{Y_i(b) < k(\alpha, b|w)\})^2|W_i] \right]
\]

\[
\leq \frac{1}{h^{L+2}} E \left[ K^2\left(\frac{W_i - w}{h}\right) (P_{1i} - p_1)^2 \left| F_{Y(b)|W}(k(\alpha, b|w)|W_i) - F_{Y(b)|W}(\bar{K}_i(\alpha, b|w)|W_i) \right| \right]
\]

\[= O(h^3),\]

33
which shows that $S_{2,n}(\alpha, b) = o_p(1)$ for all $(\alpha, b)$. Moreover, the centered process $S_{2,n}$ can be represented as

$$S_{2,n}(\alpha, b) = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} \varphi_{n,\alpha,b}(W_i, Y_i),$$

where with the same methods as in the proof of Theorem 2 below the class of functions $\mathcal{F}_n = \{\varphi_{n,\alpha,b} | (\alpha, b) \in A \times S_{L-1}\}$ can be embedded into a class $\hat{\mathcal{F}}_n = \{\hat{\varphi}_{n,c} | c \in C\}$ which is Donsker in the sense that the process

$$S_n(c) = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} \hat{\varphi}_{n,c}(W_i, Y_i), \quad c \in C,$$

weakly converges to a Gaussian process $S(c), c \in C$. Hence, weak convergence also follows for the restricted function class, i.e. for $S_{2,n}(\alpha, b), (\alpha, b) \in A \times S_{L-1}$. However, as we have shown that $S_{2,n}(\alpha, b) = o_p(1)$ for all $(\alpha, b) \in A \times S_{L-1}$, the limit is degenerate and uniform convergence follows, i.e.

$$\sup_{(\alpha, b) \in A \times S_{L-1}} |S_{2,n}(\alpha, b)| = o_p(1).$$

Similarly, it follows for the term $S_{3,n}(\alpha, b)$ (note that $\mathbb{P}(Y_i(b) < k(\alpha, b|W_i)|W_i) = \alpha$)

$$E[S_{3,n}(\alpha, b)] = O(\sqrt{nhL+6}) = o(1) ; \quad Var(S_{3,n}(\alpha, b)) = O(h^6) = o(1)$$

which shows that $S_{3,n}(\alpha, b) = o_p(1)$ for all $(\alpha, b)$. Uniform convergence, i.e. $\sup_{(\alpha, b) \in A \times S_{L-1}} |S_{2,n}(\alpha, b)| = o_p(1)$, can be shown with the same arguments as before.

Therefore we obtain from (6.1) that

$$R_n^{(1)}(\alpha, b) = -\sum_{i=1}^{n} \frac{K\left(\frac{W_i - w}{h}\right)(P_{1i} - p_1)\{I\{Y_i(b) < k(\alpha, b|W_i)\} - F_{Y_i(b)|W}(k(\alpha, b|W_i))\}}{\sqrt{nhL+2}f_{Y(b)}|P,X(k(\alpha, b|W)|W)f_W(w)\int u^2k(u)du} + o_p(1),$$

uniformly with respect to $(\alpha, b)$, and a similar argument for the remaining terms in $\hat{R}_n(\alpha, b)$ yields the assertion of Lemma 6.2. \qed

**Proof of Theorem 2** Consider for fixed $w$ the process

$$\tilde{R}_n(\alpha, b) = \frac{1}{\sqrt{n}} \sum_{i=1}^{n} \varphi_{n,\alpha,b}(W_i, Y_i)$$

where

$$\varphi_{n,\alpha,b}(W, Y) = \frac{1}{h^{(L+2)/2}}K\left(\frac{W - w}{h}\right)\left(I\{b'Y \leq k(\alpha, b | w)\} - F_{Y(b)}|W}(k(\alpha, b | W) | W)\right)$$

$$\times \left[b'(P - p) + k(\alpha, b | w)(X - x)\right]$$

34
such that
\[
\tilde{R}_n(\alpha, b) = -\frac{1}{f_{Y(b)p,X}(k(\alpha, b \mid w))} \frac{1}{w} f_{P,X}(w) \int u^2 \kappa(u) du \tilde{R}_n(\alpha, b) + o_p(1)
\]
Consider the function class
\[
\mathcal{F}_n = \{ \varphi_{\alpha, b} \mid \alpha \in \mathbb{A}, b \in \mathcal{S}_{L-1} \}.
\]
Under our assumptions, \( k(\alpha, b \mid w) \) is bounded. Hence, \( \mathcal{F}_n \) is a subclass of \( \mathcal{G}_n - \mathcal{H}_n \) defined as follows,
\[
\mathcal{G}_n = \left\{ (W, Y) \mapsto \frac{1}{h(L+2)/2} K \left( \frac{W - w}{h} \right) I \{ Y \in H \} c'(W - w) \mid H \text{ halfspace in } \mathbb{R}^{L-1}, c \in \mathbb{R}^L, ||c|| \leq C \right\}
\]
\[
\mathcal{H}_n = \left\{ (W, Y) \mapsto \frac{1}{h(L+2)/2} K \left( \frac{W - w}{h} \right) \varphi(W)c'(W - w) \mid \varphi \in C^2(\mathbb{A}), c \in \mathbb{R}^L, ||c|| \leq C \right\}
\]
for some suitable \( C > 0 \). Let \( s \) denote a constant such that \( ||W - w|| \leq s \) with probability 1 (under our assumptions the support of the covariates \( W \) is bounded).

The classes \( \mathcal{G}_1 = \{ Y \mapsto I \{ Y \in H \} \mid H \text{ halfspace in } \mathbb{R}^{L-1} \} \) and \( \mathcal{G}_2 = \{ W \mapsto c'(W - w) \mid c \in \mathbb{R}^L, ||c|| \leq C \} \) are VC-classes with (under our assumptions) constant envelopes \( \mathcal{G}_1 \equiv 1 \), \( \mathcal{G}_2 \equiv C's \) and VC-dimension \( L+1 \) and \( L+2 \), respectively, see van der Vaart and Wellner (1996), Problem 14, p. 152, and Lemma 2.6.15, p. 146. Hence, from Theorem 2.6.7, van der Vaart and Wellner (1996), p. 141, we obtain the following result for covering numbers,
\[
\sup_Q N(\varepsilon, \mathcal{G}_1, L_2(Q)) \leq d_1e^{-2L}, \quad \sup_Q N(\varepsilon C's, \mathcal{G}_2, L_2(Q)) \leq d_2e^{-(L+1)}
\]
for constants \( d_1, d_2 \) not depending on the arbitrary distribution \( Q \) of \( (W, Y) \) (such that second moments exist), nor on \( \varepsilon \).

From Kosorok (2008), proof of Theorem 9.15, p. 158, it follows for the covering number of the product class \( \mathcal{G}_1 \mathcal{G}_2 \) with envelope \( C's \) that
\[
\sup_Q N(\varepsilon C's, \mathcal{G}_1 \mathcal{G}_2, L_2(Q)) \leq \sup_Q N\left( \frac{\varepsilon}{2}, \mathcal{G}_1, L_2(Q) \right) \sup_Q N\left( \frac{\varepsilon}{2} C's, \mathcal{G}_2, L_2(Q) \right) \leq d_1d_2(\frac{\varepsilon}{2})^{-2(2L+1)}.
\]
Now, for
\[
g_n(Y, W) = \frac{1}{h(L+2)/2} K \left( \frac{W - w}{h} \right)
\]
we have \( \mathcal{G}_n = g_n \mathcal{G}_1 \mathcal{G}_2 \) with envelope \( G_n = g_n C's \) and again from Kosorok (2008), proof of Theorem 9.15., it follows that
\[
\sup_Q N(\varepsilon ||g_n|| Q C's, \mathcal{G}_n, L_2(Q)) \leq \sup_Q N(\varepsilon C's, \mathcal{G}_1 \mathcal{G}_2, L_2(Q)) \leq d_1d_2(\frac{\varepsilon}{2})^{-2(2L+1)}.
\]
Hence, it follows that
\[ \int_{0}^{\delta_n} \sup_Q \sqrt{\log N(\epsilon ||G_n||_{Q,2}, \mathcal{G}_n, L_2(Q))} \, d\epsilon \longrightarrow 0 \text{ for } \delta_n \rightarrow 0, n \rightarrow \infty. \]

Similarly, the same can be shown for the class \( \mathcal{H}_n \) where we use the same argumentation as before with \( g_n \) and \( \mathcal{G}_2 \) as before, but \( \mathcal{G}_1 = C^\beta_M(\mathcal{W}) \) with constant envelope \( M \), such that the covering number fulfills
\[ \sup_Q \log N(\epsilon, \mathcal{G}_1, L_2(Q)) \leq d \left( \frac{1}{\epsilon} \right)^{L/\beta}, \]
see van der Vaart and Wellner (1996), Theorem 2.7.1, p. 155.

Altogether, we obtain
\[ \int_{0}^{\delta_n} \sup_Q \sqrt{\log N(\epsilon ||F_n||_{Q,2}, \mathcal{F}_n, L_2(Q))} \, d\epsilon \longrightarrow 0 \text{ for } \delta_n \rightarrow 0, n \rightarrow \infty. \]

for the function class \( \mathcal{F}_n \), which is a subclass of \( \mathcal{G}_n - \mathcal{H}_n \), see Lemma 9.14 Kosorok (2008) and Lemma 16 by Nolan and Pollard (1987), where the envelope is defined as
\[ F_n(W, Y) = \frac{2C}{h^{L/2}} K \left( \frac{W - w}{h} \right) \frac{|W - w|}{h}. \]

Let \( \mathbb{P} \) denote the distribution of \( (W, Y) \) under the assumptions listed in A4. Then,
\[ \mathbb{P} F_n^2 = E[F_n(W, Y)^2] = \frac{2C}{h^{L}} \int_{\mathbb{R}^L} K^2 \left( \frac{t - w}{h} \right) \left| \frac{t - w}{h} \right|^2 f_W(t) \, dt \]
\[ = 2C \int_{\mathbb{R}^L} K^2(u) ||u||^2 f_W(w + hu) \, du = O(1). \]

Similarly, one has \( \mathbb{P} F_n^2 I\{F_n \geq \eta \sqrt{n}\} \longrightarrow 0 \) for every \( \eta > 0 \) applying \( nh^L \rightarrow \infty \).

It remains to show that
\[ \sup_{||b - \tilde{b}| \leq \delta_n, ||x - \tilde{x}| \leq \delta_n} \mathbb{P} (\varphi_{n, a, b} - \varphi_{n, \tilde{a}, \tilde{b}})^2 \longrightarrow 0 \text{ for every } \delta_n \rightarrow 0, n \rightarrow \infty. \]

A straightforward estimation yields for \( ||b - \tilde{b}|| \leq \delta_n, ||x - \tilde{x}|| \leq \delta_n, \delta_n \rightarrow 0, \)
\[ \mathbb{P} (\varphi_{n, a, b} - \varphi_{n, \tilde{a}, \tilde{b}})^2 \]
\[ \leq 2E \left[ \frac{1}{h^{L+2}} K^2 \left( \frac{W - w}{h} \right) \left( (b - \tilde{b})(P - p) + (k(\alpha, b | w) - k(\tilde{\alpha}, \tilde{b} | w))(X - x) \right)^2 \right] \]
\[ + E \left[ \frac{1}{h^{L+2}} K^2 \left( \frac{W - w}{h} \right) \left( I \{Y(b) \leq k(\alpha, b | w)\} - I \{Y(\tilde{b}) \leq k(\tilde{\alpha}, \tilde{b} | w)\} \right) - F_Y(b)W(k(\alpha, b | w) | W) + F_Y(\tilde{b})W(k(\tilde{\alpha}, \tilde{b} | w) | W) \right)^2 C^2 ||W - w||^2 \]
\[ \leq 4 \left( \delta_n^2 + \sup_{||b - \tilde{b}| \leq \delta_n, ||x - \tilde{x}| \leq \delta_n} (k(\alpha, b | w) - k(\tilde{\alpha}, \tilde{b} | w))^2 \right) E \left[ \frac{1}{h^{L}} K^2 \left( \frac{W - w}{h} \right) \frac{|W - w|^2}{h^2} \right] \]
\[ + 4E \left[ \frac{1}{h^{L}} K^2 \left( \frac{W - w}{h} \right) C^2 ||W - w||^2 \left| F_Y(b)W(k(\alpha, b | w) | W) - F_Y(\tilde{b})W(k(\tilde{\alpha}, \tilde{b} | w) | W) \right| \right] \]
\[ = o(1). \]
Then weak convergence of the (centered) process $\bar{R}_n$ to a Gaussian process follows from Theorem 2.11.22 in van der Vaart and Wellner (1996), p. 220. The calculation of the covariance structure is straightforward and therefore omitted.
